FINAL REPORT

1. Statement of Problem

The problem as stated in the original research proposal was to develop a theory of high intensity multimode gas lasers and to incorporate collision effects into the theory wherever possible. In practice, the laser theory and collision problems were studied separately. In the area of laser theory, we sought to connect previous theories of a high intensity single mode gas laser and to provide new computational methods for solving that problem which could be generalized to multimode theory. We also sought a better understanding of the physical processes occurring in high intensity lasers. Our studies of collision effects in atomic and molecular systems were strongly influenced by the rapid advances that were occurring in Doppler-free laser spectroscopy. Our goal in this area became to formulate methods by which one could use laser spectroscopic techniques to obtain both differential and total cross section data for the ground and excited states of atoms or molecules. This information could then be used in the master equations of laser theory; in this way, one could incorporate collision effects into laser theory. While working in the area of laser spectroscopy, we were led to study problems related to resonance fluorescence and laser propagation effects.

2. Content of the Report

The technical results obtained under this Grant for the period 15 August, 1973 - 30 June, 1976, have already been described in previous Progress Reports (in particular, the Progress Report for the period 1 October, 1975 - 30 June, 1976, was quite extensive). Moreover, almost all of the research carried out under this Grant has been or is in the process of being published in readily available technical journals. Consequently the remainder of this report will consist of (1) A summary of the research carried out for the period 1 July, 1976 - 31 May, 1977, (2) A brief summary of the major results obtained over the period of

the Grant, (3) a list of personnel involved in the project, and (4) a list of publications associated with the research carried out under this Grant.

3. Summary of Research Findings for the period 1 July, 1976 - 31 May, 1977

Cur study of the effects of collisions on the line shapes associated with two and three level atomic and molecular systems has been more fully developed. In an earlier publication 1, we had used a phenomenological propagator to account for the way in which collisions change the velocity associated with the populations of the various levels of the atomic system under consideration. We have been able to re-solve the problem using a somewhat more conventional and realistic propagator based on the Keilson-Storer collision kernel (see ref. 1). In doing so, we now have a theory that is valid over the entire range from "weak" to "strong" velocity-changing collisions.

The physical system under investigation consists of either two or three level atoms subject to two external laser fields and collisions with perturber atoms. One laser field (pump) is in near resonance with one of the transitions in the atoms and can excite a specific velocity ensemble of the atoms. The second laser field (probe) is in near resonance with the same or a coupled transition and probes any changes in the velocity that have occurred as a result of collisions. The line shapes involved are also sensitive to the effects of "phase-interrupting" collisions which, in turn, are related to the total elastic scattering cross sections for the various levels. Thus the line shape can serve to monitor differential (velocity-changing) and total cross sections. Both steady-state and transient type experiments were analyzed.

A simple, but not unreasonable collision model was adopted, in which collisions where "phase-interrupting" in their effect on off-diagonal density matrix elements and "velocity-changing" in their effect on diagonal density matrix elements. Within this model, we showed how to systematically

^{*}Superscripts refer to references in Section 6 of this report.

extract cross section data from the probe absorption line shape by using different pump detunings. The calculation was carried out in perturbation theory in the laser fields, but no assumption on the ratio of the detunings and widths to the Doppler width was employed. Predictions of the theory include the existence of the well known narrow saturated absorption resonance and a background "shoulder" due to velocity-changing collisions. It was also pointed out that the narrow resonance can exhibit a width with a nonlinear pressure dependence at low pressures. In a collaborative effort with the group at Orsay, France, experimental verification of various aspects of the theory has started to appear. O

Current research involves explicit numerical evaluations of the line shapes appearing in reference 1 and an explanation for the various types of structure that appear in those line shapes. Moreover, we are exploring the consequences of different collision models. For example, if the collision interaction is the same for two or three of the levels of the atoms, then collisions will be "velocity-changing" in their effect on off-diagonal density matrix elements. This type of model will lead to the possibility of line narrowing with increased pressure.

4. Brief Summary of Research Results Obtained Under the Grant

A. High Intensity Laser Theory - New computational techniques for studying the problem of a high intensity single mode gas laser were developed. Among these were a backward recursion method, an integral equation approach and direct numerical solution of the differential equation with periodic boundary conditions. Such methods should be useful in the multimode problem where conventional continued fraction techniques can not be easily applied. We were also able to connect several previous theories of the high intensity laser, providing an overall unity to these theories.

Additional insight into the physical processes occurring when two or more high intensity fields interact with atoms was obtained in a Generalized Dressed Atom Approach (GDAA). In the GDAA, we used part of

each field to "dress" the atoms and considered the interaction of the remaining interaction ("probe") with these dressed atoms. In this model we were able to semi-quantitatively predict to the position of resonances which occur in graphs of the spatially averaged population inversion in a standing wave gas laser as a function of axial atomic velocity. Such structure had been noted in previous theories, but not explained on physical grounds. As a related calculation, we were able to predict the position for multiphoton Bloch-Siegert resonances, having demonstrated the mathematical equivalence of the traveling wave stationary atom Bloch-Siegert and the standing wave moving atom laser problems. It is hoped that the GDAA will be applied to more complex systems to provide physical insight into those systems.

B. Collision Effects in Atomic and Molecular Systems - Many new and significant results were obtained in this area. A basic theory of collision effects in atomic and molecular systems d,e was applied to a number of experimental situations. In certain cases the theory was used to explain experimental results while in other cases the theory was developed in a fashion that suggests new types of experiments which could be carried out.

The theory was used to explain the intensity of photon echoes as a function of pulse delay for vibrational transitions in $\mathrm{CH}_3\mathrm{F.}^a$, f Since the transition levels in $\mathrm{CH}_3\mathrm{F}$ experience almost equal collision interaction with perturber atoms, a model of velocity-changing collisions was assumed. Such a model lends to an echo amplitude that varies exponentially as -t for small pulse separations t and as -t for longer t, in agreement with experiment. The photon echo experiment is the most direct evidence to date for velocity-changing collisions affecting off-diagonal density matrix elements. From the data, we obtained the cross section for velocity-changing collisions and the mean change in velocity per collision. This is the first experiment where both of these parameters could be determined.

In working on photon echo theory, we also established the validity conditions for using the Fokker-Planck equation as a weak collision limit of the Boltzmann equation. b,e Especially in problems involving both radiation and collisions or in problems involving initially narrow velocity distributions, one can not arbitrarily take the Fokker-Planck limit of the Boltzmann equation, as has been commonly done.

Of considerable interest has been the study of collision effects in two and three level atomic systems subject to radiation fields. i,m One field (pump) excites a specific velocity ensemble of atoms on a given transition and a second field (probe) probes the same or a coupled transition. By monitoring the probe absorption as a function of probe detuning for various pump detunings, one can obtain information on the collisional processes occurring in the various levels. The line shapes can be used in two fashions. First, systematic line shape studies can be used to extract data on both the differential and total cross section for the various levels of the transitions. Thus, excited state cross section data should be readily available for the first time. Second, the line shapes can be used to check the validity of various theories of collision effects that have been recently proposed. e We believe that, in the next few years, nonlinear optical techniques of the type described above will find an ever increasing application in the determination of collision cross sections.

- C. Resonance Fluorescence A first principle calculation of resonance fluorescence for moving atoms excited by a monochromatic laser was carried out. The frequency spectrum and fluorescence distribution were determined, supportion the notion that the laser absorption and subsequent spontaneous emission must be looked at as a single process. An experiment to measure the atomic recoil in fluorescence was proposed.
- D. <u>Self-Trapping of Laser Beams</u> A moment-theoretical approach to the theory of self trapping of lasers in plasmas was developed.^k

The approach led to a simple formulation in which the effects of saturation, the stability of propagation, and the effects of an active medium could be explored. It was found that a minimum threshold power was needed for stable beam propagation.
